## EXECUTIVE SUMMARY

In 2000 and 2001, the Alameda County Waste Management Authority (ACWMA) gathered weight data on waste disposed from over 1,500 businesses comprising four commercial waste collection routes in Oakland and Hayward. In addition, the ACWMA commissioned a waste characterization study that included analysis of the composition of waste from 260 of the businesses for which weight information was collected. This report provides a summary of the study, reports on our statistical analysis of the data, and draws conclusions regarding the data's usefulness and applicability for diversion program planning. The primary objective of this report is to apply the findings of the weight-based data as broadly as possible while understanding, and not exceeding, the limitations of the data. The goal of the project is to determine whether subsets of the data for specific industry/business groups can be used to guide the development of targeted diversion programs.

Initial business and weight data verification, correction, and organization resulted in over 12,000 valid weight records for over 1,500 businesses representing 83 Standard Industrial Classification business groupings. Initially, we grouped businesses into the 38 categories used by the California Integrated Waste Management Board in their Statewide Waste Characterization Study. Statistical analysis, however, identified some groups where data were not well distributed. Manipulation of the groupings resulted in the 48 business groups used throughout this study. These are further grouped into four larger categories: Manufacturing; Retail and Wholesale; Service; and, Miscellaneous Businesses.

Mean weekly weight and mean waste density were calculated and are summarized in Figures ES1 and ES-2. In general, where there is a close similarity of the mean weights or densities between several business groups, there is no statistical difference between these groups. Figure ES-1 indicates that there are several business groups within each of the four major business categories that have distinctly higher or lower mean weights.

Waste and business attribute data are analyzed in the report to indicate the degree to which they may be used for extrapolation or general application (Table ES-1). Waste data include weekly mean waste weight and density; business attributes include number of employees and gross sales. We determined the consistency or efficacy of the data through the calculation of statistical "confidence." Strength of confidence was determined through examination of data variability in proportion to the number of observations and average values. Where variability in the data is relatively low, there is greater confidence that the data is representative of that business group. We have strong confidence in the mean weekly weight calculated for twelve business groups; moderate confidence in the mean weekly weight for 26 groups, and weak confidence in the
mean weekly weight for ten groups (the mean weekly weight derived for these ten groups should be used with little confidence).

Further analysis of the waste weight and business attributes included determination of the strength of relationships between waste data and business attributes (Table ES-1). Correlation coefficients were calculated for each of four possible relationships: weight vs number of employees; weight vs gross sales; density vs number of employees; and, density vs gross sales. 23 of the 48 business groups showed a strong or moderate positive correlation between waste weight and number of employees; in other words, for these groups, waste weight can be predicted with strong to moderate confidence based on the number of employees. Only thirteen of the 48 showed strong or moderate correlations between waste weight and gross sales, and fewer still showed strong or moderate correlations between waste density and business attributes. Very few groups showed inverse relationships between waste and business data (e.g., when the number of employees goes up, waste weight goes down). A few businesses, however, did exhibit moderate negative correlations between waste density and business attributes.

Based on the mean weekly weight for each of the 48 business groups, and the number of businesses within each of these groups in all of Alameda County, we were able to predict the total amount of waste produced in the County each year by each business group (Table ES-2). The yellow shading in Table ES-2 indicates the six business groups that we predict contribute at least five percent of the total disposed commercial waste in the County: Miscellaneous Construction; Retail Restaurants; Business Services; Engineering and Accounting Services; Medical Services; and Real Estate Services. Please note that we calculated strong or moderate confidence in the mean weekly weight for all six of these business groups (Table ES-1). Table ES-2 also indicates by blue shading the nine other business groups that we predict contribute between two and five percent of the County's disposed commercial waste. We calculated strong or moderate confidence in the mean weekly weight for seven of these nine groups (all but Miscellaneous Agriculture/Fisheries and Personal Services .

Based on mean weekly weight and the number of employees in each business group (as reported in a countywide business database), we were able to calculate the average per employee waste generation rate for each of the 48 business groups. These are shown in Table ES-2 and in Figures ES-3 and ES-4. There is considerable variability in the per employee generation rate between business groups, from a low of less than 500 pounds per year to a high of nearly 7,000 pounds. This represents a range of difference of more than an order of magnitude. It should be recalled, however, that these figures are only reliable to the extent of the strength of the mean weekly waste disposal figure calculated for each of the business groups. The major business category with the lowest per employee figure is manufacturing, at just over 1,000 pounds per employee per year, while Retail/Wholesale had the highest figure, at just over 2,500 pounds per year (Figure ES-3).

In addition to the weight data, we analyzed waste composition data for 260 businesses included in the weight-based data collection effort to determine the typical waste composition of each of the 48 business groups. The analysis shows the differences in composition between business groups, and indicates where the best opportunities remain for diversion program development. For
several of the business groups, however, too few samples were collected to produce reliable statistical results. The average waste composition for the six business groups that represent the highest amount of disposed commercial waste in the County (see Table ES-2) are shown in graphic format in Figures ES 5a-5f. Note the large amounts of mixed paper, other paper, and food waste in most of the composition charts. Film plastics and other plastics are also significant fractions of the waste of these business types. Please note that not all of these waste characterizations are statistically reliable, due to small sample sizes.

We performed statistical analysis of waste weight for each of the weekly collections and for each of the collection routes to determine whether the time of year or route location influenced waste attributes. There is no apparent relationship between the time of year and the amount of waste collected. There are, however, significant differences between waste weight, business attributes, and waste composition for the four collection routes. Two routes tended to be mostly similar (273 \& 274), but the other two routes ( $271 \& 295$ ) were significantly distinct from each other and significantly different from the other two as well. It is likely that differences in waste weight and composition are due primarily to differences in business distribution and business attributes between the four routes. This exemplifies the need to use adequate knowledge of business types and attributes when extrapolating waste information from one area to another - random extrapolation of waste data will likely result in erroneous predictions or assumptions of waste characteristics.

We used waste composition data, mean weekly disposed weight data, and information on the kinds of businesses located in each of Alameda County's jurisdictions to develop profiles of commercial waste for each jurisdiction. This information is preliminary and requires crosschecking with other sources, but it can be a useful planning tool for developing commercial diversion programs throughout the County.

## SECTION I

## INTRODUCTION

## BACKGROUND, SCOPE, AND PURPOSE

The Alameda County Waste Management Authority (ACWMA) seeks to develop public education, recycling and source reduction programs to assist Alameda County jurisdictions in reaching the locally mandated 75 percent diversion rate by the year 2010. To achieve this, the ACWMA and Source Reduction and Recycling Board have initiated several related studies, including the 2000 Waste Characterization Study and the Waste Production Measurement Study. The ACWMA has also been conducting a Weight-Based Disposal Research Project, in cooperation with Waste Management of Alameda County and LTS Scales, to measure actual weights of disposed materials at a variety of County businesses. Weight data was collected from individual business loads over a one-year period along four commercial routes in Oakland and Hayward (Figure 1). The current report is intended to complete the Weight-Based Disposal Research Project by evaluating, interpreting, and applying the collected weight data.

This evaluation is intended to determine whether detailed information on the weight of waste can be used as a basis for diversion program design throughout the County, and to use statistical methods to ensure that the use of such data has a firm scientific basis. The primary objective of this report is to apply the findings of the weight-based data as broadly as possible while understanding, and not exceeding, the limitations of the data. The goal of the project is to determine whether subsets of the data for specific industry/business groups can be used to guide the development of targeted diversion programs.

ESA was not involved in the data-gathering phase of this project. ESA's involvement has been limited to rectifying and analyzing data that was collected by other parties. While ACWMA made the ESA team aware of issues involved with the data collection, ESA has of necessity relied on data provided by other parties in conducting the analysis that forms the basis of this report.

During 1999 the California Integrated Waste Management Board (CIWMB) conducted a statewide study ${ }^{1}$, the primary objective of which was to obtain information on the types and amounts of materials being disposed in the state. This effort included gathering samples from a total of 1,207 commercial establishments, and recording density and composition data for each sample. The results were then extrapolated to the entire state. To some extent, the statewide study overlaps with the current study, in that both collected and analyzed waste composition data from individual businesses that were then applied statistically to all businesses of the same type.

[^0]The current study, however, differs from the statewide study in that actual weights were recorded at the time of regular refuse collection over a one-year period. To our knowledge, this study marks the fist time that such detailed and extensive records of the weights of refuse from individual businesses have been gathered and analyzed.

## SECTION II

## METHODOLOGY

The data that forms the basis of this report were collected through a joint effort of ACWMA staff, Waste Management of Alameda County, and LTS Scales. The ACWMA contracted with Waste Management of Waste Management of Alameda County and LTS Scales to have on-board scales placed on four front loader commercial collection vehicles. The vehicles equipped with the scales were assigned to four commercial routes, three in Oakland and one in Hayward (Figure 1). The drivers of the trucks were given a logbook of businesses whose setouts they were to weigh throughout the approximately one-year period, beginning in May, 2000 and ending in June, 2000. One week each month the drivers weighed all of the businesses on their route. For each lift, scales recorded the gross weight of the filled dumpster, and then the tare weight of the empty dumpster. The resulting net weight was derived by subtracting the tare weight from the gross weight.

In conjunction with the weight collection effort, the ACWMA contracted with R.W. Beck, consultants, to characterize the waste from 300 of the businesses whose refuse was being weighed. Waste from the designated businesses was collected and sorted into its constituent material types.

ESA conducted three major steps to rectify and then analyze the weight-based data provided by the ACWMA. These three steps, which are described in detail below, were, first, to verify and where necessary exclude faulty weight records; second, to add data on business attributes, including SIC code, number of employees, and gross sales to the list of businesses from which waste was collected and weighed; and third, to perform statistical analysis of the data.

## VERIFYING THE WEIGHT DATA

ACWMA staff had already taken steps to eliminate faulty, irrelevant, and incomplete weight records prior to handing the weight database over to ESA. ACWMA staff eliminated from the study weight records of businesses not targeted in the study, including multi-family residences. ACWMA and ESA both refined the data set by eliminating incomplete or faulty weekly weight records. A weekly weight record is defined as the sum of the weights of all individual collections from a particular business for an entire week. While the majority of businesses included in the study had one bin collected once per week, some businesses had multiple bins, and about 300 had their waste collected two, three, four, or five times per week. If a weekly weight record for a business with more than one pick-up per week was missing a weight or had a faulty weight for one pick-up, the record was still deemed complete; any more than one miss from a weeks' collections resulted in exclusion of the weight record from the database.

Other weight records were excluded because the scale could not obtain a good reading (designation of " x " in the scale record); because of a tare weight greater than the gross weight, resulting in a negative number for the net weight, or because there was an obvious error in the weight record, such as a net weight of ten thousand pounds for a one or two yard bin. Weight records for businesses for which an SIC code could not be obtained were also excluded. The original data set contained approximately 19,000 weekly weight records. The final database contains 12,763 verified weekly weight records.

## POPULATING THE BUSINESS DATABASE

ACWMA staff compiled a database, based on account records provided by Waste Management of Alameda County, of the 1,583 businesses from which wastes were collected and weighed. In addition, ACWMA staff populated the database with SIC code information from the iMarket database (primary source is Dunn and Bradstreet) for some of the businesses. The database, as received from the ACWMA, contained no information regarding the businesses' employee count or gross sales data. ESA gathered the following information from the following sources:

1. SIC code, number of employees, and gross sales information from the iMarket database;
2. For businesses which were either not listed in iMarket or had incomplete iMarket listings, we telephoned the businesses to determine business type (to determine SIC code) and employee count. The search included telephone books and internet research to find telephone numbers for those businesses without contact information in either the ACWMA data or the iMarket data; and,
3. For businesses which remained unclassified after the above steps were performed, we droveby the business's address to determine, where possible, the business type from the activities that could be observed occurring at the site.

After the discovery of incorrect SIC information in the original database received from ACWMA, ESA staff compared 1,063 SIC codes in the ACWMA data with the iMarket database. We either phoned, researched on the internet, or drove by businesses not in iMarket to determine their SIC code. In the end, the database contained SIC codes for 1,512 businesses; number of employee data for 1,270 businesses, and gross sales data for 1,080 businesses. Businesses for which SIC codes could not be obtained, and their weight records, were excluded from further analysis.

ACWMA provided ESA with waste characterization data for 300 businesses, obtained by sorting a single load from each of the businesses. ESA was able, however, to match only 260 of the 300 with businesses included in the weight records database. Waste characterization data for the remaining 40 businesses was therefore excluded from the analysis.

## STATISTICAL METHODS

## EXPERIMENTAL DESIGN AND APPROACH

ESA performed five basic kinds of assessments on the business waste data with statistical methods:

1. Data suitability and consistency to achieve appropriate business grouping;
2. Efficacy of data for general applications or extrapolation to a larger study area;
3. Relationships between variables to predict waste material information from estimated or known values in the study area;
4. Characterization of waste composition; and,
5. Influences of other factors such as time of year and geographic distribution of businesses.

Data suitability analyses determined a grouping scheme for all the businesses that emphasizes confidence in predictability of variables from the samples. The goal was to organize the data into business groups that met two criteria: the groupings would be based on SIC codes that define business groups based on the nature of the business; and, the groupings would provide sufficient, and suitable, data per group to derive summary information on variables (e.g., mean weight per week, waste density, business attributes, or waste composition) with an acceptable level of confidence that the data represent the business group.

Efficacy of Weight and Business Data was performed to provide a measure of the strength of confidence in the data for the business groups delineated above. The goal was to provide some relative measure of how "good" the data were for general information or extrapolation to other areas, or for other analysis - i.e., the "dependability" of the data. The variability of data within each business group was compared to the average variability to provide this relative measure of data strength.

Relationships Between Variables were assessed to determine whether the values of one or more variables could be predicted from the mean values of other variables or influencing factor. For example, whether the total net weight of the waste from a particular business group could be predicted from knowledge of the number of employees or gross sales.

Waste Characterization provided information of the percentages of different materials in the waste. Mean values and variability were used to determine which materials comprised the greatest percentage for business groups, and for other variables.

Influences of Other Factors were assessed to indicate whether variable means were influenced by the time of year, or the geographic location of the waste collections. The time of year was determined by the week in which the observations were collected. The geographic location of
the collection was determined by segregation of data from the route followed by four different waste collectors.

## STATISTICAL ANALYSIS

Business Grouping, Data Consistency and Efficacy of Weight and Business Data were estimated from Descriptive Statistics, Distribution Statistics, and Comparative Statistics. Descriptive Statistics summarized information of the variables to assess the strength of confidence in the data; Distribution Statistics show how data variability were distributed to gain insights into the nature of data variability related to business types or other variables; and Comparative Statistics were used to show whether summary information (e.g., variable means) were significantly different from each other - this comparison is used to determine whether business groupings could (or should) be combined or split into smaller groups to improve overall confidence in the information summarized from a business group.

Descriptive Statistics were calculated for all variables for each business group.
Variables for each business group included the following:

- Total Net Weight (the weight of waste from each business per week as measured and reported);
- Waste Density (calculated from the TotalNetWt and a calculation of the volume of service for each business based on the bin size and frequency of pick-ups (information obtained from Waste Management of Alameda County);
- Number of Employees (as reported in the I-Market database or through ESA telephone inquiries);
- Gross Sales (as reported in the I-Market database); and,
- Percent Composition (as derived from sort data for selected businesses throughout the sample area).

For each variable, descriptive statistics include the mean, standard error, and count (\# of observations in that group - where an observation is each weekly weight). The mean represents the predicted value of that variable for that business group; the standard error represents the variability expected in the means from the businesses in the group; and the count gives an indication of the amount of data in the sample for the business group. The amount of variability and size of the sample provide an estimate of the confidence in the mean value to represent that business group. A large standard error, usually coupled with a small count relative to the mean and the other business data, would indicate weak confidence in the mean as representative of the business group. A small standard error, usually with a large count, indicated strong confidence in the mean as representative of the group for that variable.

Distribution Statistics included Frequency Histograms and Univariate Scattergrams plotted for each business group. These charts demonstrate how the observations for each variable are distributed from low to high values. It was important to determine whether the data were normally distributed (bell-shaped) - an assumption necessary when used in the kinds of statistical analysis used in this study - or of some other form that might indicate the values are erroneous or being influenced by other factors. A bimodal histogram, for example (which was apparent in some of the original business groups) would indicate that some factor is causing a group of the data not to fit a normal distribution (e.g., a business, or perhaps an unrelated group of observations, within the groups that has distinctively higher values than the rest of the group.

Scattergrams were used when histograms indicated bimodality in the data to find the source of the high value grouping within the business group. Scattergrams were used to show where each observation value is located for each business within a group. Observations, or groups of observations, that seemed to be outliers were investigated. When an outlier was determined to be an erroneous value, it was eliminated from the dataset. When appropriate, an entire business was eliminated from the dataset because the values causing bimodality in the group belonged to a business with attributes indicating unsuitability for that group (e.g., the wrong kind of waste composition, or clearly erroneous business information on number of employees or gross sales).

Comparative Statistics included unpaired t -tests of the differences in means of major variables between each business group; and cell bar charts with confidence intervals of the mean to provide graphic representation and to demonstrate differences between business groups. Differences in variable means were considered significant at $90 \%$ confidence level (i.e., when $p<$ $0.1)$. Accordingly, for bar charts demonstrating comparisons of variable means, differences were significant when $90 \%$ confidence intervals did not overlap (i.e., overlapping confidence intervals indicated the two means were not significantly different at the $90 \%$ confidence level).

The results of Comparative Statistics provided additional information to group businesses and to interpret and extrapolate data from the samples to the study area. If business groups had significantly different means for weight or business variables, there was little support to combine those groups to improve the group integrity. When business groups, however, did not have significantly different means, there was evidence that those groups could be combined (with other justification such as reasonable similarity in the nature of the business)to improve the consistency of values within the group (i.e., lower variability and achieve better data distribution) and thus the confidence that that variable mean is representative of the group for the study area. Examination of cell bar charts with $90 \%$ confidence intervals also provides a visual interpretation of the suitability of the data since large confidence intervals, like large standard errors, indicate high variability and weak confidence in the suitability of the data to represent the mean for that business group.

Relationships Between Variables were connoted from correlation coefficients and bivariate scattergrams of variable means. The correlation coefficients were calculated to show the arithmetic relationship of each variable to each other variable for each business group. For example, a correlation coefficient for TotalNetWt and \# Employees would, for a particular business group, show whether high values for TotalNetWt corresponded to high values for \#

Employees. A high correlation coefficient, indicating a strong relationship between these two variables, would provide evidence that the TotalNetWt could be predicted from the \# Employees for that business group. In our analysis, if the correlation coefficient were above .5 , we considered the relationship to be strong for that group; a value between .3 and .5 indicated a possible, but weak, relationship; a value below . 3 indicated no relationship between those variables. Bivariate scattergrams were used to show how the distribution of observations affect the correlations. For example, when a business group showed little or no correlation between two variables, but such a correlation was expected, the scattergram would identify which business/observations were not in conformance with a relationship between those variables (i.e., potential outliers). When used in conjunction with univariate scattergrams of distribution, observations that did not "fit" well, and seemed to contradict reasonable expectations would be suspected as outliers and investigated further to determine their suitability to represent the business group.

Waste Characterization used descriptive statistics to derive mean percentages of waste materials for each business group. The most common materials were plotted with $90 \%$ confidence intervals to ascertain valid (significant) differences in materials for business groups and to demonstrate the efficacy of sort data.

Influences of Other Factors were assessed from further grouping of each business group by each potential influencing factor (i.e., week of collection and route). Descriptive statistics were calculated and displayed to compare mean variable values and relative variability to determine whether there were significant differences in variables between groups. Cell bar charts indicated whether variable means were significantly different between groups of influencing factors at the $90 \%$ confidence level (e.g., whether TotalNetWt differed between the four routes).

## SECTION III

## RESULTS AND DISCUSSION

## 1. DATA VERIFICATION, BUSINESS GROUPING, AND DATA CONSISTENCY

As described in the methodology section, prior to data analysis several steps were performed to verify the weight-based data, and to add information on business type and business attributes to the database. The size of the final dataset is shown in the final five columns of Table 1. In all, there were 12,763 valid weekly weight records (and the same number of density records) representing the waste of 1,512 businesses with confirmed Standard Industrial Classification (SIC) codes. Of these businesses, the dataset includes information on number of employees for 1,270 businesses and information on annual gross sales for 1,080 businesses. Waste composition data were gathered for 300 businesses, but only 260 of these could be matched with a business for which weight and SIC code data were available.

All of the businesses from the study were initially organized into 38 business groups corresponding to those devised by the California Integrated Waste Management Board (CIWMB, 2001). The 38 CIWMB groups were collated from the 83 major business groups as designated by 2-digit Standard Industrial Classification (SIC) codes. This initiated our business grouping with categories of businesses that were of similar "waste streams," according to the CIWMB analysis, though many groups were "catch all" groups of less similar business (e.g., Manufacturing: Other, which includes six 2 -digit SIC code groups, including Tobacco Products, Stone, Clay, Glass, and Concrete Products, and Petroleum Refining ).

We performed two layers of data analysis to reorganize the business groups into groups that provided the best organization to represent the data for further analysis. The first analysis used descriptive statistics to identify business groups that might require lumping with other groups or spitting into one or more groups to maximize data consistency for further analysis and to represent the business waste county-wide. The second run used univariate scattergrams to identify data, or data from entire businesses, from within the groups that may be incorrectly included in the dataset (i.e., outliers). Further examination of outliers would result in elimination of data or businesses that were determined erroneous.

## BUSINESS GROUPING

Descriptive statistics, giving information of the mean, variability, and distribution of weight and density of waste from the data, were analyzed for the initial 38 groups. Business groups with high variability (SE), with a high count (high number of observations), and with a histogram
indicating bimodal or uneven distribution were examined in greater detail to determine if the group should be split into two or more groups with less variability and a more "normal" distribution. Five CIWMB groups that were so identified included the following:

- Finance, Insurance, Real Estate, and Legal - which included 8 SIC groups;
- Manufacturing Other - which included 6 SIC groups;
- Retail Other - which included 3 SIC groups;
- Services Other Misc - which included 5 SIC groups; and,
- Services Other Professional - which included 3 SIC groups.

The data from these 25 SIC groups were examined further with $t$-tests of weight and density to determine which groups were significantly "different" from others. We also wanted to combine reasonably similar business groups (e.g., we didn't combine Insurance Agents with Museums even though their data were not significantly different). These 25 SIC groups were reorganized into a total of 15 business groups - many of the groups were lumped with others to create larger groups of similar data and waste stream expectation, but several were left as a single 2-digit SIC code group.

Business groups that had a small count, despite having a low standard error, were also examined as candidates for combining with other businesses with similar waste weights and densities - the goal would be to create larger groups with related business natures and similar waste material. For example, the CIWMB group Retail Trade: General Merchandise Stores was only represented by one sample, so this group (which only had one 2-digit SIC group) was combined with Retail Trade: Other (which had 3 SIC code groups, but one had been split - see above).

The process of splitting, combining, and recombining resulted in selection of a total of 48 business groups for further analysis (Table 1).

## DATA CONSISTENCY

Univariate scattergrams of weight and density indicated individual weight samples from individual businesses, and groups of weights from an entire business group or subgroup, that seemed to vary considerably from the other samples from within one of the 48 business groups. Several individual weight outliers were identified and examined further to assess whether the data were appropriate - this resulted in elimination of only 3 individual samples from the dataset. The remaining obvious outlier shown on Figure 2, a weight sample nearly twice the weight of any other samples, was retained because it was determined that an unusually high weight might properly represent such a "business" (Oakland Army Base), and that this business was properly designated within the Public Administration group. Further, the scattergram of density (Figure 2) does not indicate that this unusually high weight was also of unusually high density so the waste weight could have been accurate.

When an entire set of waste weights or density from one business seemed disproportionately high, it was also examined for attributes that would account for the values (e.g., high number of employees or high gross sales within a group that showed a correlation of these with weight). The following businesses were identified with these grouped outliers:

- a Real Estate business ( SIC 6514.00);
- a Holding \& Other Investment Office (SIC 6799.99);
- Asian Neighborhood (Service, Other);
- Horizon Service (Service, Other);
- City Center Plaza (Service, Professional); and,
- Consulting Engineers (Service, Professional).

Only one entire "business," City Center Plaza, was eliminated from the dataset. Other businesses, although with higher than usual waste weights, were retained because after checking their data further it was determined they were properly classified and the weights might be reasonable, based on reasonable relationships to number of employees or gross sales. City Center Plaza was grouped as a Professional Service with only 12 employees, but the waste was unusually heavy and contained a high proportion of food waste. Further investigation revealed that City Center Plaza is actually a group of mostly fast food restaurants (about 10) and a few miscellaneous retail businesses - not a professional service group. Since there was no appropriate place for City Center Plaza within any of the business groups without introducing erroneous business data on gross sales, number of employees, as well as mixed business types within one data group, the City Center Plaza data was deleted from the dataset.

## 2. EFFICACY OF WEIGHT AND BUSINESS DATA

Table 2 provides an overview of the relative strength of the confidence in mean values for waste weight and density, as well as for business data including number of employees and gross sales. Examination of Table 2 reveals that several business groups continue to have weak confidence in the data (i.e., groups with mostly green shading across), while other groups have strong confidence in the data (groups with mostly yellow shading). Confidence in both waste weight data (weight and density) as well as in Business Attributes (number of employees and gross sales) are given. High confidence in both kinds of information is required to use either kind of information to make assumptions about the other (e.g., both gross sales and waste weight must have high confidence in order to assume that high gross sales create high waste weight for a particular business group).

Groups with particularly strong confidence in both waste weight information and business attributes (i.e., strong statistic for three or all four data variables include the following:

Strong Statistic in Four Variables
Manufacturing-Metal
Miscellaneous-Construction
Miscellaneous-Trucking
Retail/wholesale-Durables

Strong Statistic in Three Variables<br>Retail-Restaurants<br>Retail/wholesale-Food<br>Retail/wholesale-Nondurables<br>Services-Auto Repair

Predictions of waste material and business attributes for these eight business groups will have the strongest confidence of those in the study.

There were no groups with weak statistics in all four variable categories. Groups with particularly weak confidence in both waste weight and business attributes (i.e., weak in three categories) include:

- Misc-Transportation Air
- Retail/wholesale-Stone
- Services-Finance (Lite)
- Services-Miscellaneous
- Services-Personal

Predictions of waste material and business attributes for these five business groups will have the weakest confidence of those in the study. These groups are basically those that remain with small numbers of observations despite attempts to group them to improve data consistency (as described above). Although grouping left these groups with small numbers of observations and high variability, they did not fit well with any other groups - i.e., they would have reduced confidence in other groupings or their business nature was inappropriate.

Examination of Cell Bar Charts showing $90 \%$ confidence intervals provides comparative visualization of the strength of confidence in waste weight and density data for the 48 business groups (Figures 3, 4, \& 5). Figure 3 shows how business groups within the four sub groups (manufacturing, miscellaneous, retail/wholesale, and services) compare. The $90 \%$ confidence intervals are shown as error bars extending above the value bar (i.e., upper confidence interval); the error bar also extends downward into the colored bar but cannot be seen on the chart (lower confidence interval). The $90 \%$ confidence interval indicates that the mean value has a $90 \%$ probability of being within the interval (i.e., the error bar upper and lower). Therefore, if two bars' confidence intervals overlap, there is a $90 \%$ probability that the means are the same (i.e., not different). Figures 3,4 , and 5 indicates whether business groups' waste weights or densities are significantly different from one another.

As Figure 3 shows, many groups are significantly different. For example, within the manufacturing groups, the Food manufacturers group clearly has the highest waste weight, and the confidence interval is small enough that even the lower end is well above the next highest upper limit (Wood manufacturers). Looking back to Table 2, note that MfrFood has moderate confidence in the waste and business data (i.e., mostly blue shading); this "moderate" confidence
is reflected in the size of the confidence interval bar in Figure 3. In this example, although the mean values were considered "moderate" in Table 2 because of the variability of values among the observations, the values were significantly higher than other businesses within that subgroup. Many businesses within the manufacturing subgroup had mean values that were not significantly different even though the mean values seemed different. Electric, Furniture, Transportation, and Wood manufacturers represent four groups that have significantly higher values than the other groups (although all are significantly lower than Food), but they are not significantly different from each other. Chemicals, Instruments and Misc., Machinery, Metal, Print, Textile manufacturers have significantly lower mean weights than the other businesses, but they are not significantly different from each other. Thus it can be seen that many of the business groups fall into bunches of weights that are significantly higher or lower than others, and within those bunches there may be several business groups, or just a single higher or lower group (e.g., Food Manufacturers).

Though several business groups seem to have substantially higher mean waste weights than other businesses within their subgroup (e.g., AgFish, TransAir, WhslStone), the confidence intervals are so large that those values are not significantly different than other high weight businesses. As noted above, TransAir and WhslStone were among those with weak confidence in the waste weight and business attributes (from Table 2); those observations are substantiated by Figure 3 which shows that those seemingly higher values are not really significantly different from other businesses with much lower mean values. As with the manufacturing groups described above, the other subgroups have bunches of groups with values that are significantly different from each other (i.e., higher values and lower values).

An arrangement of the businesses in order of increasing mean waste weight and density (Figures $4 \& 5$ ) shows more clearly which businesses fall within lower or higher waste weight or density bunches, but does not show the arrangement within the four subgroups. The Personal and Financial-Light Services clearly have the lowest mean weights, with values significantly lower than any other businesses. Although Food manufacturers was clearly the highest mean weight within the manufacturing category, several other groups with high values are shown as not significantly different from Food (i.e., WhlsStone, MiscAgFish, MiscTransAir). These groups are, however, the same groups noted above with high values, large confidence intervals, and weak confidence in the values (which is why they cannot be distinguished from each other). Food has significantly higher waste weight than all of the other business groups.

Examination of waste density values organized in increasing order provides expected results (Figure 5). Businesses with significantly higher waste densities include Rwhsl-Stone, RetBldg, and MiscAgFish -- all of which are likely to contain high density items such as concrete, stone, metals, and wood products. The group with the highest density, Miscellaneous Services, is not as expected, but the error bar is large, indicating high variability, so it is likely that this group contained some very high density wastes observations that might be considered outliers - the nature of the group is, however, poorly defined and determination of outliers could not be made. As such, this group (SvcMisc) has very weak confidence, is poorly defined, likely contains erroneous data, and is not recommended for use in predictions.

Business groups with significantly lower density wastes include Retail Apparel, Utilities, Medical Services, TransAir, Communication, Finance Avg, and Public Administration - all groups likely to have low density wastes. Most of the business groups fall within a large moderate level density bunch with little or no significant difference within this cluster.

## 3. RELATIONSHIPS BETWEEN VARIABLES

Examination of the relationships between business waste data (weight and density) and business attributes (employees and gross sales) indicates whether waste weight and density can be predicted from knowledge of business attributes. This would be useful, since data on business attributes are frequently updated, are relatively comprehensive, and are readily available from published sources, such as iMarket. Correlations between waste data and business attributes show whether positive or negative relationships might exist between business attributes and waste data for the 48 business groups in this study (Table 3 and Figure 6). Correlation coefficients (rsq'd) range from -1 to +1 , with -1 being a perfect negative correlation (inverse relationship) and +1 being a perfect positive correlation. Correlation coefficients therefore that are near -1 or +1 show a strong correlation, whereas coefficients near 0 are very weak relationships. For business groups where a strong correlation exists, predictions of waste materials from business attributes are warranted.

As Table 3 shows, strong correlations exist for several business groups. The following groups have particularly high ( $>0.5$ ) correlation coefficients that indicate a relationship between waste weight and business attributes.

## Manufacturers:

Electrical,
Instruments and Miscellaneous, Transportation.

## Miscellaneous Businesses.

Agriculture and fishery, Communication, Air Transportation.

## Retail \& Wholesale Businesses:

Furniture,
Restaurants,
Stone Products.

## Services:

Financial (average size), Medical, Miscellaneous, Personal Services, Social Services.

For all of these groups, the strong correlation is positive (when waste weight goes up, so does the \# of employees or gross sales). There were also about an equal number of business groups with moderate ( $>0.3,<0.5$ ) correlation coefficients, indicating a likely relationship, but not as strong as with the above groups. For these businesses, it is possible to predict that when the business size (i.e., gross sales and \# of employees) is larger, the weight of the waste is higher.

There were few positive correlations between waste density and business attributes. This is expected, for there are few situations where a larger business might generate more dense materials (compactor accounts were not included in the dataset).

There were no strong negative correlations of any kind for any groups. Very few businesses showed an even moderate inverse relationship between waste weight and business attributes. Several groups, however, show inverse relationships between waste density and business attributes. These included the following:

Mfr - Furniture,
Mfr - Paper Products,
Mfr - Wood Products,
Misc - Agriculture \& Fishery,
Misc - Education, and
Retail/Wholesale - Building.
For these groups, it is reasonable to predict that when the business size (i.e., gross sales and \# of employees) is larger, the density of the waste is less. This may indicate that larger businesses tend to have lighter waste, or that they oversubscribe to refuse service, and tend not to fill up their dumpsters as much as smaller businesses do.

## 4. WASTE CHARACTERIZATION

Table 4 summarizes the percentage of waste within each of the 46 waste types for the four major business categories (Manufacturing, Miscellaneous, Retail/Wholesale, and Services). Table 4a shows the waste composition for all 48 business groups, but combines waste types into 19 categories of waste. The standard error for the mean percent of waste weight given in these tables provides an indication of the variability of sort data for each business group. Differences in sort data among the four main business subgroups are comparatively represented in Figures 7, a, b, c, d, \&e. Figure 7a shows the 19 waste categories in order of decreasing percentage of total weight: for each waste category, each of the four major business categories' percent of that waste category is shown for comparison.

Figure 7a indicates that there are only moderate differences in composition between the major business categories, especially given the relatively large standard errors observed. Other Paper was higher in composition than any other waste category; however, it was not significantly higher (at $90 \%$ confidence level) than the second highest, Food Wastes. Uncoated Corrugated, Other Organics, Film Plastics, and Wood-Unpainted basically tied with Food Wastes for second highest composition at $90 \%$ confidence level. A group of five categories were significantly lower (at $90 \%$ level) than the rest of the categories: Recyclable Glass, HDPE/PET, Other Glass, Steel Food and Beverage Cans, and Aluminum Cans. The remaining eight sort categories occupy a group of middle percentages that are not different from each other.

The waste categories that represent the smallest percentage of wastes, Steel Food and Beverage Cans, and Aluminum Cans, had no significant differences between major business groups.

Examination of Tables 7 (b,c,d,e) provides comparisons of waste categories within each business group. As with the other cell bar charts above, the sort categories tend to fall into higher and lower bunches of significantly different percentages of the waste weight. Wood-Unpainted percentages were significantly higher for Manufacturing and Retail/Wholesale groups than for Miscellaneous and Services business groups. Inerts were significantly higher for Services than for Manufacturing and Retail/Wholesale. And Yard Wastes were significantly higher for Miscellaneous groups than for Manufacturing groups.

For Manufacturing groups (Figure 7b ), Unpainted Wood seems to be significantly the highest, but Other Paper, Food Waste, Film Plastics and Other Metals are also high and not significantly different from each other or Unpainted Wood; but, as a group they are significantly higher than the other categories. Recyclable glass, Other Glass, Aluminum Cans and Steel Food and Beverage Cans were significantly lower than the rest.

For Miscellaneous groups (Figure 7c), Other Paper seems to be significantly the highest, with Yard Wastes, Food Wastes, and Other Organics also in a higher percentage bunch. Unpainted Wood is in a middle bunch. Aluminum and Steel Cans again were significantly the lowest.

For Retail/Wholesale groups (Figure 7d), the overall trend from highest to lowest percentages seems to follow the "All Businesses Combined" analysis that established the order of categories (see Figure 7f). . There are basically three bunches that are significantly different from each other: the highest percentage is shared by the top 7 categories; the lowest percentages bunch includes the 5 lowest categories; and the rest are in a middle bunch.

For Service groups (Figure 7e), Other paper is the highest, but sharing that highest percentage bunch with Food Wastes and Inerts, both of which have large error bars that do not separate them from Other Paper. Aluminum and Steel Cans are the lowest, and High Grade paper joins HDPE/PET, Other Glass, and Recyclable Glass in a next to the lowest bunch.

In summary, the $90 \%$ confidence intervals show that in general there are few significant differences between percentages of waste weight categories between the major business categories, but as with waste weight data in general (see Figure 3 for example), significant differences appear in clumps of categories within which differences are not significant. Some categories clearly dominate the wastes, with one or a few categories showing significantly higher percentages than the rest within each major business category almost in every major business group.

Waste composition for each of the 48 business groups is shown in Table 4a. Table 4a reveals that the waste composition of most of the business groups is at least ten percent Other Paper; few groups have less than 5 percent Other Paper in their waste. Other material categories that make up a large proportion of the waste of many or most of the business groups include Corrugated Cardboard (OCC), Film Plastics, Food Waste, Wood-Unpainted, and Other Organics. Material
categories that are usually a small proportion of the waste include HDPE/PET containers, Recyclable Glass, Other Glass, and Aluminum and Steel Cans.

Where few waste sorts were performed for a particular business group, the standard error tends to be high relative to the waste composition figure, indicating a large amount of variability in the sample. Where only one sample was sorted, the standard error is 0.0 , indicating no variability (and that the sample is statistically meaningless). Business groups with large numbers of sorts tend to have standard errors that are relatively small. Note, for example, the low standard errors for RwhslDur (Retail/Wholesale Durable), which had 27 sorts, and the high standard errors for SvcHotel (Services: Hotels), which had only 3 sorts. In general, the composition data for business groups with 3 or fewer sorts should be considered unreliable. The following business groups had 3 or fewer sorts:

No Sorts

- MfrStone
- MfrTextl
- MfrTrans
- Misc AmuseRecPks
- Misc MovieMuseum

1-3 Sorts

- MfrElect
- MfrFurn
- MfrRubber
- Misc AgFish
- Misc Commun
- Misc Educ
- Misc Utils
- RetAppar
- RetAuto
- RetBldg
- RetRestr
- RwhslStone
- SvcFineLite
- SvcHotel
- SvcMedic
- SvcMisc
- SvcPers

## 5. INFLUENCES OF OTHER FACTORS --ROUTE AND TIME OF YEAR

Histograms of Total Net Weight and Density of wastes for the combined businesses were examined for evidence of influences of the time of year of the waste samples or the route within which the samples were taken. There was no observed trend or effect of the time of year on weight or density of waste samples - most of the error bars overlapped and minor differences were scattered throughout the year. There were however, significant differences among the routes for waste weights and densities (Figure 8). Further analysis of differences among the
routes revealed there were also significant differences in business gross sales and number of employees (Figure 8) and in waste composition.

Values for mean weight, density, number of employees, and gross sales with standard errors are given in Table 5. Figure 8 more clearly shows the nature of the differences among the collection routes for waste weight and density, and for business gross sales and number of employees. These descriptions are summarized for each route as follows:

- Route 271. Route 271 consistently had the largest confidence interval, indicating that this route had smaller samples or higher variability in kinds of businesses. This route had significantly higher mean weight than the other routes, and shared the highest density with route 274. Route 271 was not different from other routes in business characteristics.
- Route 273. Route 273 was not significantly different from the other routes, thoug it did have slightly higher weight and slightly lower density. This route had, however, the highest number of employees per businesses, a significant difference from the other three routes, which were all the same in this regard.
- Route 274. Route 274 was not significantly different from other routes for any comparison category. This route tended to have slightly higher values than others, but never the highest.
- Route 295. Route 295, which included part of Hayward, was almost a mirror image of Route 271 statistically, except for the number of employees, where they both shared the lowest value. Route 295 had the lowest waste weight and density, the highest gross sales, and the lowest number of employees (shared with route 271 as noted).

Examination of waste composition data also revealed significant differences among the four collection routes (Figure 9). In Figure 9, the information is arranged in decreasing order of total percent of waste weights for all businesses. Figure 9 indicates, for the nineteen material categories, which routes have greater or less influence on those percentages. The five largest composition groups vary with routes as summarized here:

- Other Paper. Slight differences, not very significant, decreasing with 271, 273, and 274; but with 295 clearly, and significantly at $90 \%$, the lowest percentage.
- Food Waste. Route 271 seems the highest but large confidence intervals overlap every route, so there are no significant differences within this category.
- Uncoated Corrugated. No differences among routes 271, 273, and 274 - but 295 (previously the lowest percent in the two higher categories) clearly has the significantly highest value for this category.
- Other Organics. No significant difference between any routes.
- Wood-Unpainted. Similar to Uncoated Corrugated, with 295 again the highest, but only significantly higher than 271.
- Inerts. Route 271 is significantly the lowest.
- High Grade paper. Route 271 is significantly the lowest, and 295 the highest.
- Other categories had no significant differences between routes.

Notable observations of waste compositions for the routes derived from Figure 9 include the following for each route:

- Route 271. Clearly dominated by Other Paper and Food wastes, which were also the two overall highest composition categories for all routes combined. In contrast, route 271 had lowest values for Coated Uncorrugated, Wood Unpainted, Inerts, and High Grade Paper.
- Route 273. Was not significantly different from other routes in any composition category. In general, percentages tended to follow the general trend for all businesses combined.
- Route 274. Generally followed the overall trend like route 273, but stood out as having the highest percentage of Inerts of all routes, although because of large confidence interval, this is only significantly different than the lowest route for inerts (271).
- Route 295. Tended to mirror route 271 in most composition categories (i.e., inverse relationship - one is high the other low, etc.). As such, 295 was the lowest for both Other Paper and Food, and the highest for Uncoated corrugated and Wood (i.e., exactly the opposite of 271). Otherwise, this route followed the general trend, except for High Grade paper, where route 295 was clearly and significantly the highest of all routes.

Significant differences among the collection routes indicate several aspects of the waste characterization dataset. First, the differences demonstrate that differing composition of commercial areas in different geographical locations is likely to produce waste with differing composition and character (just as different types of businesses produce different types of waste.) Differences may be in overall weights, density, or in composition. Extrapolation of waste characteristics from one geographic location to another, even within a small area of the County, would have to be done with caution.

Second, the differences in waste weights and densities seem to correspond to, or explain, differences in business characteristics and in waste composition. For example, route 271 had the highest percentages of Other Paper and Food wastes, but low percentages of Uncoated Corrugated and Wood Unpainted - these differences would account for the high waste weight and density for 271 compared to other routes. When extrapolating waste characteristics from one area to another, it is therefore preferable to extrapolate individual business groups' data to reduce errors caused by expected differences in business characteristics.

Third, differences in waste weights, business attributes, and waste composition among the four routes demonstrate that the study encompassed a variety of business attributes and waste characteristics, and therefore, as a whole, may be representative of at least portions of the rest of the County. If, for example, all four routes had shown no differences in waste characteristics or
business attributes, we could assume there was no difference from one area to another throughout the County; but that may have been an erroneous assumption, for it is just as likely that the lack of differences were due to all four routes being within a small geographical area of similar businesses that do not represent the variety within the rest of the County. Further subsampling throughout the County would be required to determine to what extent the sample is representative of the entire County. However, our analysis, showing clearly significant differences between the routes, demonstrates that the four routes encompassed more than one kind of geographical "pocket" of business types. The potential error of the sample not including businesses' waste characteristics that represent the entire County is therefore less than if there were no differences among the routes.

## 6. EXTRAPOLATION OF THE RESULTS

Table 6 compares two attributes of businesses within the study sample to data for the County as a whole. The first five columns show the number of employees in businesses within each group in the study sample, and the percent of the whole that this represents; the number of employees in each group in the entire iMarket database for Alameda County, and the percent of the whole that this represents; and the difference, plus or minus, between the two percentage figures. The next five columns provide the same comparison for the number of individual businesses within each business group.

This table demonstrates the similarities and differences of the composition of the study sample with the composition of the whole commercial sector in Alameda County. Green shading indicates business groups for which the sample size significantly under-represents the prevalence of that business group in the County. Green shading is applied if the percent of the whole sample represented by a business group is less than half of the percent of the whole county represented by that business group. For example, Manufacturing - Transportation businesses account for about 1 percent of all employees in Alameda County, but only about 4 percent of the sample. Since .4 is less than one half of 1 , we applied green shading to these cells in the table. Overall, the table indicates that the business composition of the sample is fairly reflective of the composition of Alameda County businesses as a whole: only 13 of the 48 categories are seriously underrepresented (in terms of number of employees). Most of the under-represented business groups are services. Manufacturing in the sample is more prominently represented than in the County as a whole. Several important retail groups are not well represented, including food, apparel, furniture, and restaurants. Only 3.9 percent of the businesses in the County, representing only 2.4 percent of employees, fall into the "Other" category, and so have no representation in the study sample.

We used the number of businesses in each business group in Alameda County and the mean weekly weight for each business group to predict the total annual tons disposed by the businesses in each group for the County. The results appear in Table 7 (Note that the tons per year figure for All Groups is slightly different than the sum of the tons per year for all of the individual groups, since the first figure is based on the mean for the entire sample.) The predicted total amount of waste disposed by all Alameda County businesses in one year is about 728,000 tons. The
business groups within the County that are predicted to dispose of the most waste are Miscellaneous Construction, Retail Restaurants, Business Services, Engineering/Accounting Services, Medical Services, and Real Estate Services. Together, these six groups account for about 44 percent of the weight of disposed commercial waste in Alameda County. We calculated strong or moderate confidence in the mean weekly weight for all six of these business groups (Table 2), indicating the reliability of these figures. Nine other business groups (blue shaded in Table 7) account for an additional 26 percent of predicted County commercial waste disposal.

Based on mean weekly weight and the number of employees in each business group in the entire County (as reported in iMarket), we were able to calculate the average per employee waste generation rate for each of the 48 business groups. These are shown in Table 7. There is considerable variability in the per employee generation rate between business groups, from a low of less than 500 pounds per year to a high of nearly 7,000 pounds. This represents a range of difference of more than an order of magnitude. The major business category with the lowest per employee figure is manufacturing, at just over 1,000 pounds per employee per year, while Retail/Wholesale had the highest figure, at just over 2,500 pounds per employee per year.

The weight per employee figures are only reliable to the extent of the strength of the mean weekly waste disposal figure calculated for each of the business groups, and the strength of the correlation between number of employees and weight. There are sixteen business groups which have moderate or strong statistics in both mean weight and the correlation of number of employees to weight. For these sixteen groups, the weight per employee figure may be used with a reasonable degree of confidence. These are:

| Manufacturing | $\underline{\text { Miscellaneous }}$ | $\underline{\text { Retail }}$ | $\underline{\text { Services }}$ |
| :--- | :--- | :--- | :--- |
| Furniture | Communications | Auto | Financial - Average |
| Instruments- Misc. | Movies/Museums | Furniture | Financial - Light |
| Machinery |  | Restaurants | Medical |
| Metal |  |  | Real Estate |
| Paper |  | Social |  |
| Textiles |  |  |  |

Based on the composition of the commercial sector of each of the 14 cities in Alameda County (and several unincorporated communities) and the mean weekly weight for each business group, we were able to predict the amount of waste disposed by each of the 48 business groups in each city. The results of these calculations are shown in Tables 8a through 8p. Since the mean weights for businesses were derived from the study sample, which only included commercial routes in Hayward and Oakland, the figures should be used as indicators only.

## SECTION IV

## SUMMARY, CONCLUSIONS AND NEED FOR FURTHER RESEARCH

## SUMMARY OF RESULTS

All businesses were organized into 38 groups according to California Integrated Waste Management Board (CIWMB) classification system based on SIC business groupings. Initial statistical analysis of data variability and distribution identified some groups where data were not well distributed and reorganization of several SIC codes into new groups was performed to improve data consistency (i.e., splitting and lumping to reduce variability within business groups). A few observations (waste weights) and one business were eliminated from the data because their variability from a normal distribution could not be accounted for. This process resulted in the businesses in the study being organized into 48 business groups. These 48 groups were further lumped into the following four categories for some analyses: Manufacturing; Retail and Wholesale; Service; and Miscellaneous Businesses.

Variability of the final data were further summarized to display the efficacy of waste and business attribute data for the final business groups. Waste data included weekly mean waste weight and density; business attributes include number of employees and gross sales. Efficacy was determine from the strength of confidence that the data as representative of the business group. Strength of confidence was determined through examination of data variability in proportion to the number of observations and average values. Lower variability in the data will allow greater confidence that the data is representative of that business group. The strength of the four descriptive statistics for each business group is shown in Table 9. Mean waste weights and densities for the 48 groups were also plotted with $90 \%$ confidence intervals to visually compare the results of waste data and the significance of differences between data for the business groups.

Further analysis of the waste weight and business attributes included determination of the degree of relationships between waste data and business data. Knowledge of the relationships, together with knowledge of the strength of the data, will provide the confidence in making extrapolations of waste predictions from business attributes - such as predicting a waste weight or density from knowledge of business type and attributes such as number of employees or gross sales. Correlation coefficients were calculated for each of four possible relationships between waste data and business attributes (weight vs \# employees; weight vs gross sales; density vs \# employees; and, density vs gross sales). Twenty-eight business groups showed a strong or moderate positive correlation between waste and business data (Table 10). For these groups, predictions of waste characteristics from knowledge of business data would be appropriate, although the strength of data should also be taken into consideration regarding confidence in such
extrapolations. Very few groups showed inverse relationships between waste and business data (e.g., when \# of employees goes up, waste weight goes down). A few businesses, however, did identify moderate negative correlations between waste density and business attributes.

Waste composition data were analyzed to determine the efficacy of the data and relationships of waste materials to business grouping attributes. Some categories clearly dominate the waste: other paper was significantly higher in composition than any other waste category; food wastes, uncoated corrugated, other organics, and film plastics basically tied for second highest category although mean values were different, they were not significantly different at the $90 \%$ confidence level. This analysis showed that there were often, but not always, significant differences between waste composition for business groups. Other paper, for example, the highest waste category for all groups combined, was not the highest for Retail/Wholesale groups, where it was exceeded by both uncoated corrugated and wood unpainted (which is fifth overall).

Because the data were collected from four geographically distinct routes within Alameda County, and over a period of one year, in weekly collections, it was prudent to ascertain whether the location of time of year influenced the amount or kind of waste discarded. Cell bar charts with $90 \%$ confidence intervals of total waste weight for each of the weekly collections and for each of the collection routes revealed the following: there did not seem to be any relationship between the time of year and the amount of waste collected; and, there were significant differences between waste weight for the four collection routes. Further examination of route waste collections revealed several differences between the routes including mean weight, density, and waste composition. Two routes tended to be mostly similar ( $273 \& 274$ ), but the other two routes (271 \& 295) were significantly distinct from each other and significantly different from the other two as well. It is likely that differences in waste weight and composition are due primarily to differences in business distribution and business attributes amoung the four routes. These differences demonstrate the patchiness of business data within the study area and show how this affects waste attributes. This knowledge exemplifies the need to use adequate knowledge of business types and attributes when extrapolating waste information from one area to another random extrapolation of waste data will likely result in erroneous predictions or assumptions of waste attributes.

## CONCLUSIONS

For many of the business groups, mean weight and density are statistically robust enough to be meaningful; that is, they can be used to predict the weight of wastes for other businesses of the same type (Tables 9 and 10). Therefore, within the study area, the analysis of the weight-based data can be used with a reasonable level of confidence for planning diversion programs. Likewise, the waste characterization data for many of the business groups has reasonable consistency, both internally and with other waste characterization studies, and can be considered a useful planning tool. Since, however, the data were not gathered from a random sample, but rather from selected routes, it is difficult to say if the analysis can be applied more broadly, to the rest of Oakland and Hayward, to other cities in the County, and beyond.

One reasonable interpretation of the results is that the data may adequately represent much of Alameda County's commercial sector, even without random sampling. This interpretation is based on the observed variability, within a reasonable range, of weights and other attributes, between the four collection routes included in the study. This impression, however, can only be confirmed through additional research (see below).

The analysis indicates a moderate to strong correlation for most of the business groups between number of employees and mean weekly weight of the waste collected. For sixteen of the business groups - those with moderate or strong correlations between number of employees and weight, and with moderate to strong means for weight, the weight per employee figure (Table 7) is probably an adequate measure for planning purposes.

Correlations between gross sales and waste weight are strong for only a few business groups, and generally gross sales does not appear to be a good predictor of weight waste. The analysis does, however, indicate a weak negative correlation between gross sales and density, and also between number of employees and density. This may be due to larger businesses producing lighter waste, or to a tendency among larger businesses not to fill up their dumpsters as much as smaller businesses.

The analysis shows that for some business groups, there was insufficient data to produce reliable, meaningful statistics. Some groups are under-represented relative to their prevalence in the Oakland and Hayward, and in Alameda County as a whole. Some groups simply had too few businesses, or too few weight records, to produce strong statistics.

## FURTHER RESEARCH

Three areas are suggested for further research. The first is a targeted random sampling of weights of individual waste collections for businesses throughout Alameda County. A study of this kind would show the extent to which the current study can be applied more broadly, and could also be used to strengthen the statistics for some business groups.

A second area for further research is the fullness of commercial refuse containers when they are collected. Development of "fullness factors" would correct for variations in the derived density of collections, and may reveal trends in over-subscription to refuse collection service.

Finally, the results of this study should be compared to the results of the CIWMB's statewide waste characterization study, particularly the waste composition figures and the weight per employee figures.

## SECTION VI

## GLOSSARY

The glossary contains explanations of statistical terms used in the text.
confidence interval (C.I.) A range of values such that there is a known probability that the true value of some quantity lies within that range. For example, the $90 \%$ C.I. for a mean represents a range of values within which we expect to find the true value of the mean $90 \%$ of the time.
correlation coefficient (R2) A quantitative measure of the relationship between two variables. Correlation coefficients range from -1 to +1 ; a value of +1 , indicating that large values of one variable are exactly associated with large values of another variable; a value of -1 , indicating that large values of one are exactly associated with small values of the other (an inverse relationship); a 0 value indicates the arithmetic absence of any relationship. The level of correlation that is practically significant varies with the situation, but generally if the correlation coefficient is greater than 0.5 , the relationship probably has some basis.
descriptive statistics Computations that summarize data rather than making comparisons between data, its sources, or relative objectives.
error bar The extension of a single point on a graph to reflect the variability of the quantity being estimated.
group A collection of cases in a dataset that share the value of a variable. For example, a variable describing a person's gender divides the data into two group levels: male and female.
histogram A bar chart that plots the distribution of a variable.
mean The sum of the observations divided by the number of observations (i.e., the arithmetic average).
outliers Observations that are distant from the bulk of the data; they can be discarded or corrected if they arise from an obvious error in data collection, or are designated in an incorrect group.
$\boldsymbol{p}$ value A quantitative estimate of the likelihood of an observation, or observed difference in values, occurring by chance. This likelihood is expressed as a decimal such that, for example, a value of 0.01 means it is a one in 100 chance (one percent) that such a difference occurs by chance; a larger $p$ value, 0.1 for example, means that it is a ten in 100 ( 10 percent) chance that the difference occurs by chance.
standard error (S.E.) A statistic that estimates the variability in the sample mean you expect if you take repeated samples of the same size from the population. A large S.E. relative to the mean indicates high variability, and thus weak confidence in how well the mean represents the
population; a low S.E. relative to the mean indicates low variability, and thus strong confidence in the mean.
t-test (unpaired) An analysis that compares the means of two groups and determines the likelihood of the difference occurring by chance. The chance is reported as the $p$ value.

## TABLES

## TABLE 1: BUSINESS GROUPS AND DATA SETS

Table 1 lists each of the business group designations used in the study and defines the types of businesses included in each group. The first column, Business Group, is the name of the group used throughout this study. The second column, SIC Codes, shows which Standard Industrial Classification codes are included in the group. The third column, Description, describes the types of businesses within these SIC designations. The fourth column, CIWMB SIC Groupings, indicates how the group was determined: it was either taken directly from the groupings of SIC Codes used by the CIWMB, or derived from the CIWMB groups by splitting particular SIC codes out of an existing group, or through a combination of splitting apart one or more CIWMB groups and then lumping those SIC codes into a new group. The final five columns show the size of the samples used in the study for each group: the total number of weekly weight records; the number of individual businesses in each group; the number of businesses in each group for which we have data on the number of employees; the number of businesses in each group for which we have data on gross sales; and the number of businesses in each group for which we have waste characterization data.

## TABLE 2: DESCRIPTIVE STATISTICS FOR WASTE WEIGHT AND BUSINESS ATTRIBUTES

Table 2 shows several descriptive statistics for the forty-eight business groups. The table is divided into two sections: Waste Weight Information and Business Information. Throughout the table, yellow shading indicates a strong confidence in representation of the mean; blue shading indicates moderate confidence; and green shading indicates little or no confidence. The strength of the statistical relationship is determined by calculating the ratio of the standard error to the mean and comparing that ratio to the average ratio for all businesses. For weight and density, if the ratio is less than .06 , the statistic is considered strong, between .06 and .1 moderate, and greater than .1 weak. For number of employees, the cutoffs are: less than .07 the statistic is considered strong, between .07 and .12 moderate, and greater than .12 weak. For gross sales, the cutoffs are: less than .09 the statistic is considered strong, between .09 and .16 moderate, and greater than .16 weak. This categorization strategy was developed to indicate to the reader where the data are weak, strong, or moderate for each business group.

In the first part of the table, Waste Weight Information, the mean weekly weight and mean density of collections are given, as well as the Standard Error for each mean. A strong statistic in these categories indicates a good clustering (low variability and normal distribution) of weight records within a business group (see Figure 2), and suggests that the mean is a reliable predictor for the weight or density of all businesses represented by the sample. (This information is also graphically shown in Figures 3, 4 and 5.) This part of Table 2 also shows the number of individual weekly weight records for each group (the "Count" column).

The Business Attributes section of Table 2 shows the statistical strength of the data from the IMarket database for the number of employees per business and the gross sales per business for each of the forty-eight business groups. Again, a yellow shading indicates a strong statistic, suggesting that the mean is a good predictor for the number of employees or gross sales per business for all businesses of this type.

The Count columns in Table 2 show the number of individual records used in the analyses. Weight and Density have the same count, since density is derived from the weight records and account information for each business showing the total weekly volume of waste service (the number of containers multiplied by the volume of containers multiplied by the number of collections per week). The counts for number of employees and gross sales in each group is "weighted" because the figure represents the sum of the number of employees or gross sales for each business multiplied by the number of weekly weight records for that business.

TABLE 2
DESCRIPTIVE STATISTICS FOR WASTE WEIGHT AND BUSINESS ATTRIBUTES

Indicates strong statistic Indicates weak statistic
Indicates moderate statistic

## TABLE 3: CORRELATIONS OF WASTE WEIGHT AND DENSITY WITH BUSINESS ATTRIBUTES

Table 3 is a table of correlations. The data in Table 3 is also represented graphically in Figure 6 . A statistical correlation shows the degree to which the value from one data set predicts the value from another related data set. For example, in the first column of Table 3, Net Wt vs Number of Employees, the correlation shows the extent to which the number of employees in a particular business can be used to predict the weekly weight of the business's waste. Correlations are expressed as $r$-sq'd (r-squared, or $r^{2}$ ): the range of possible values is from -1 to 1 . A higher positive r -squared (a positive decimal closer to 1 ) indicates a better positive correlation, in other words, a greater likelihood that the value of one type of data will predict another. For example, for MfrElect (Electrical Manufacturers), there is a strong positive correlation between net weight and gross sales, indicating that, within this business group, businesses with higher gross sales tend also to have higher weekly waste weights.

A negative $r$-squared is referred to as a negative correlation, and indicates an inverse relationship between two data sets. For example, for MfrWood (Wood Manufacturers) there is a moderate negative correlation between the number of employees in businesses within this category, and the density of the waste that the businesses produce. In other words, for businesses of this type, the more employees, the less dense the waste.

In this table, yellow shading indicates a strong positive or negative correlation (r-squared above 0.50 and below -0.50 ; as it happens, there are no strong negative correlations); blue shading indicates a moderate positive or negative correlation ( r -squared between 0.30 and 0.50 , and between -0.30 and -0.50 ) and green shading indicates a weak or non-existent correlation (r-squared between -0.30 and 0.30 ).

## TABLE 4: WASTE COMPOSITION FOR THE FOUR MAJOR BUSINESS GROUPS

Table 4 shows the average composition of waste for each of the four major business categories used in the Study, and for all groups combined. For each business category, for each material type, the percent composition and the standard error are shown.

## TABLE 4A: WASTE COMPOSITION

Table 4a shows, for each of the 48 business groups, the proportion of disposed waste represented by nineteen material types. The 19 material types are composites of the 46 types for which data was collected. This data is derived from waste sorts of 260 businesses included in the weight study. In the table, any material type that represents 10 percent or more of a business group's waste is shaded yellow, and any material type that represents between 5 and 10 percent is shaded blue. The last column in this table shows the number of businesses included in the waste sort for each group ( $\mathrm{n}=\mathrm{x}$ ). For each material type for each business group, the percent composition and the standard error are shown. The standard error provides an indication of the variability of the data in each group. The higher the standard error, the more variable the data. Business groups that only had one sort $(\mathrm{n}=1)$ have a standard error of zero, since there is no variability in the data.

The following materials categories are composites:

| Composite Category | Consisting Of |
| :--- | :--- |
| Newspaper/Magazines | Newspaper, Magazines |
| Other Paper | Text Books, Phonebooks, Other Paper |
| HDPE/PET | HDPE Bottles-Natural, HDPE Bottles- <br> Colored, HDPE - Wide, PET- Slim, PET- <br> Wide |
| Other Plastic | Other Plastic Containers, Mixed Plastic |
| Recyclable Glass | CRV Glass, Other Recyclable Glass- Colored, <br> Other Recyclable Glass- Clear |
| Other Metals | Other Non-Ferrous Metals, Other Ferrous <br> Metals, <br> White Goods |
| Yard Waste | Leaves and Grass, Branches and Stumps, <br> Prunings and Trimmings |
| Other Organics | Tires, Other Rubber, Wood-Painted, Textiles <br> and Leather, Diapers, Other Organic Waste |
| Inerts | Crushable Inerts, Other Inerts |
| Other Waste | Gypsum Wallboard - Painted, Gypsum <br> Wallboard - Unpainted, Asphalt Roofing, <br> Household Hazardous Waste, Brown Goods, <br> Composite Bulky Items <br> Carpet, Miscellaneous Fines |

Notes：Blanks indicate no sort data was gathered for this business group．
Key：$\quad$ Material comprises at least $10 \%$ of total for this group
Material comprises between $5 \%$ and $10 \%$ of total for this group
Material comprises less than $5 \%$ of total for this group

## TABLE 5: DESCRIPTIVE STATISTICS OF WASTE WEIGHT AND BUSINESS INFORMATION, BY COLLECTION ROUTE

Table 5 compares descriptive statistics for the four collection routes included in the study. This table shows the variability of four factors: weekly weight, density, gross sales, and number of employees, for weighed samples and business attributes for all of the businesses on the four routes included in the study. The table further breaks down each route into the four major business groups: manufacturing, miscellaneous, retail/wholesale, and service. The last set of columns, All Groups Combined, shows the combined data for all four major business groups; this information is also shown graphically in Figure 8.

Throughout Table 5, green shading indicates the lowest value among the four routes (not including All Routes) and yellow shading represents the highest value among the four. For example, for mean weekly weight for manufacturing groups, route 273 had the highest mean weight, route 271 had the highest standard error, and route 295 had the highest number of samples ( n ).

Table 5 indicates that, overall, the data is fairly consistent. For example, the mean weekly weights for manufacturing and miscellaneous groups from all four routes are quite consistent. However, for retail/wholesale, route 271 had a weight considerably higher than the mean for all groups, and route 295 had a weight considerably smaller than the mean.

This table indicates the problematic nature of Route 271. For all groups, for both weight and density, route 271 had the fewest number of samples, the largest standard error, and the most "highest" values for mean weight and density.

 satavi

## TABLE 6: COMPARISON OF STUDY SAMPLE TO COUNTYWIDE DATA

Table 6 compares two attributes of businesses within the study sample to data for the County as a whole. The first five columns show the number of employees in businesses within each group in the study sample, and the percent of the whole that this represents; the number of employees in each group in the entire iMarket database for Alameda County, and the percent of the whole that this represents; and the difference, plus or minus, between the two percentage figures. The next five columns provide the same comparison for the number of individual businesses within each business group.

Green shading in the table indicates business groups for which the sample size significantly under-represents the prevalence of that business group in the County. Green shading is applied if the percent of the whole sample represented by a business group is less than half of the percent of the whole county represented by that business group. For example, Manufacturing Transportation businesses account for about 1 percent of all employees in Alameda County, but only about .4 percent of the sample. Since .4 is less than one half of 1 , we applied green shading to these cells in the table.

## TABLE 7: COMMERCIAL WASTE DISPOSAL IN ALAMEDA COUNTY

Table 7 shows, for each of the 48 business groups, the predicted amount of waste produced in the County each year by each business group. These figures are achieved by multiplying the number of businesses in each group by the mean weekly waste weight for that group (Table 2), and multiplying this product by 52 ( 52 weeks in a year). The yellow shading in Table 7 indicates the six business groups that we predict contribute at least five percent of the total disposed commercial waste in the County: Miscellaneous Construction; Retail Restaurants; Business Services; Engineering and Accounting Services; Medical Services; and Real Estate Services. Table 6 also indicates by blue shading the nine other business groups that we predict contribute between two and five percent of the County's disposed commercial waste.

Table 7 also shows the average per employee waste generation rate for each of the 48 business groups. These figures are derived by dividing the predicted annual disposal for a business group by the number of employees in that group. There is considerable variability in the per employee generation rate between business groups, from a low of less than 500 pounds per year to a high of nearly 7,000 pounds. This represents a range of difference of more than an order of magnitude. It should be recalled, however, that these figures are only reliable to the extent of the strength of the mean weekly waste disposal figure calculated for each of the business groups. The major business category with the lowest per employee figure is manufacturing, at just over 1,000 pounds per employee per year, while Retail/Wholesale had the highest figure, at just over 2,500 pounds per year.

Notes: /1/ Calculated by multiplying mean weekly disposed weight by number of businesses in group and number of weeks in one year.

## TABLE 8: COMMERCIAL WASTE DISPOSAL IN ALAMEDA COUNTY CITIES

Table 8a-o shows, for each city in the County and for the unincorporated area the number of businesses within each of the 48 business groups and the predicted weight of the waste disposed each year by each business group. Waste weight is derived by multiplying the mean weekly disposed waste weight by the number of businesses in the business group, and multiplying this product by 52 (as there are 52 weeks in one year). In each table, the business groups that represent at least 5 percent of total disposed weight are shaded yellow, and those that represent between 2 and 5 percent are shaded blue.

## FIGURE 2: SCATTERGRAMS OF WEIGHT AND DENSITY FOR EACH BUSINESS GROUP

Figure 2 includes two scattergrams, the top one for weight and the bottom one for density. Each colored dot in the scattergrams represents an individual weekly weight or density record, or observation. The scattergrams show in graphic format the degree to which observations cluster in each business group. For example, in the top scattergram, all but one of the weight observations for Misc PubAdmin (Miscellaneous Public Administration) overlap to form a continuous line. The exception, which is near the top of the chart, is a single observation from the Oakland Army Base. This lone observation indicates a weekly weight record of about 13,000 pounds, and is either due to an error in data gathering or recording or to an extraordinarily heavy collection event.

Other business groups indicate some degree of "bimodality." For example, MfrFood (Manufacturing - Food) has several observations which are disconnected from the others. This may indicate that one or more businesses in the study were producing considerably more waste than the other businesses in this group. Other business groups that show bimodality are Misc Construc (Miscellaneous Construction) and RwhslFood (Retail-Wholesale Food). There is considerably more bimodality in the density records than in the weight records. This may result from the varying levels of "fullness" in dumpsters from collection to collection and from week to week (since densities are calculated by dividing the weekly weight record by the service level of waste collection, expressed in cubic yards, and do not include a "fullness" factor).

In general, groups with tight, consistent clustering of observations will produce more robust and reliable statistics than groups with scattered observations or bimodality. See the discussion of Table 2.

## FIGURE 3: MEAN WEEKLY WEIGHT AND DENSITY

Figure 3 presents weight and density data from Table 2 in graphic format. The top bar chart in Figure 3 shows, in alphabetical order within the four major business categories, the mean weekly weight of waste collections for each of the 48 business groups. The error bars (the "T" on top of each solid colored bar) are statistical calculations that indicate the likely range in which the actual value falls at a $90 \%$ confidence level. Only the top half of each error bar is shown on the figure, but each error bar also projects below the top of its colored bar an equal distance downward into the colored bar. For example, the error bar for weight for MfrChem (Manufacturing Chemicals) extends from the top of the solid blue bar, at about 400 pounds per week, almost to 500 pounds per week; the part of the error bar not shown would extend down the same distance, or to about 300 pounds per week. With the $90 \%$ confidence interval used in this study, this chart indicates that for all chemical manufacturing businesses represented by those included in this study, there is a $90 \%$ chance that the mean weekly weight of their waste is between 300 and 500 pounds. Where error bars overlap between business groups, there is statistically no difference between values.

BAR CIARTS OF TOTAL NET WEGGITT AND DENSITY FOR WASTE FROM ALI, BUSINESSES IN GROUPS

## FIGURE 4: MEAN WEEKLY WEIGHT, ARRANGED IN ORDER OF INCREASING VALUES

Figure 4 presents the same information as the top part of Figure 3, but the business groups are arranged in order of increasing value. This figure shows that the business group with the lowest mean of measured weekly weights was SvcPers (Services - Personal) and that the highest was MfrFood (Manufacturing - Food). Error bars show the range in which the actual mean for all businesses represented by the sample would fall, given the $90 \%$ confidence interval.

## FIGURE 5: MEAN DENSITY, ARRANGED IN ORDER OF INCREASING VALUES

Figure 5 presents the same information as the bottom part of Figure 3, but the business groups are arranged in order of increasing value. This figure shows that the business group with the lowest mean of measured density was Ret Appar (Retail - Apparel) and that the highest was SvcMisc (Services -- Miscellaneous). Note the very large error bar for SvcMisc and the similarity of densities for the majority of business groups in the middle of the chart.

## FIGURE 6: CORRELATIONS

Figure 6 presents the same information as Table 3, but in a graphic format. In this figure, positive correlations are indicated by bars that begin at and extend above a horizontal line (the zero ( 0 ) line). The higher the bar extends toward 1.00 , the stronger the positive correlation. Negative correlations are indicated by bars that begin at and extend below a horizontal line. The lower the bar extends toward -1.00 , the stronger the negative correlation.

FIGURE 6 CORRELATION CHARTS

## FIGURE 7: WASTE COMPOSITION

Figures 7a, b, c, d, e, and f summarize the same data presented in Table 4.
Figure 7a compares the waste composition of the four major business groups. Error bars show the 90 percent confidence interval.

Figures $7 \mathrm{~b}, \mathrm{c}, \mathrm{d}$, and e show the percentage of each of the 19 agglomerated waste categories for each of the four major business groups. Again, error bars show the 90 percent confidence interval. Figure 7 f shows the percentage of each waste category for all groups combined.

## FIGURE 8: VARIABILITY BETWEEN THE FOUR COLLECTION ROUTES

Figure 8 shows the differences between the four collection routes for mean weekly weight, density, gross sales, and number of employees for all business groups. The error bars show the range within which the actual mean falls, given the $90 \%$ confidence interval.

Figure 8 demonstrates the range of variability between the routes. The Total Net Weight bar graph shows that among the four routes, one has a significantly higher value, one has a significantly lower value, and the other two are statistically the same. Even with this variation, the range of difference is quite small: the mean weight for the lightest, route 295 , is about $72 \%$ of the mean weight for the heaviest, route 271 (lowest mean is 449.5 ; highest is 621.2 ; see Table 5).

Figure 8 and Table 5 suggest that there may be a sufficient range of variability between the routes to support a conclusion that the four routes are reasonably representative of fairly broad range of commercial collection routes in the County. This would be true if the four routes essentially equate to a statistically representative random sampling of all collection routes within the County. This conclusion can, however, only be confirmed through additional research.

[^1]
## FIGURE 9: WASTE COMPOSITION SHOWING DIFFERENCES BETWEEN COLLECTION ROUTES

Figure 9 compares the proportion of the nineteen composite waste categories (see Table 4a) for businesses from the four collection routes. The error bars show the range in which the actual mean falls, given the $90 \%$ confidence interval (recall that the error bars extend down below the top of the bar the same distance that they extend above it). The relatively large error bars indicate the high variability in waste composition within each route.

[^2]
[^0]:    ${ }^{1}$ California Integrated Waste Management Board, Statewide Waste Characterization Study: Results and Final Report. Sacramento: CIWMB, December, 1999.

[^1]:    Notes. As with other bar graphs in this report, the $90 \% \mathrm{Cl}$ (which go into the bar as well as above) can be used to indicate the relative significance of the means - overlapping bars indicate that the means are not different, whereas when error bars to not overlap. the means are significantly different at $90 \%$ confidence.
